Mechanism for Privacy Preserving Public Auditing for Shared Data in Cloud

Pooja Kapadne, Deepak Sharma
Department of Computer Science, K. J. Somaiya College of Engineering, Vidyavihar, Mumbai, Maharashtra, India

Abstract: ***Today growing technologies and services have gave the profound platform to new technique called cloud computing. Cloud computing is gaining immense importance in today's' business and organizational platforms due to availability of required resources to the user anytime-anywhere. Sharing data among multiple users is perhaps one of the most engaging features that motivate cloud storage. Therefore, it is also necessary to ensure the integrity of shared data in the cloud is correct. The data stored on cloud is subject to skepticism due to existence of hardware and software failure and human errors. Moreover Cloud Service Provider (CSP) may not inform data owner about its data loss to safeguard its reputation and business. So, there is a need for a mechanism to allow data owner and public verifier to efficiently audit cloud data integrity without retrieving the entire data from the cloud. In addition it must not reveal the identity of the signer on each block of data to the public verifier. The new public auditing scheme for shared data with efficient user revocation in the cloud is proposed so that the semi-trusted cloud can re-sign the blocks that were previously signed by the revoked user with the valid proxy re-signatures, when a user in the group is revoked. Ring signatures are used to compute the verification metadata needed to audit the correctness of shared data. The introduced mechanism is able to perform multiple auditing tasks simultaneously instead of verifying them one by one.***

Keywords: **Cloud computing, public auditing, privacy preserving, public verifier, ring signatures.**

I. INTRODUCTION

Cloud computing is one if the hottest buzzwords in technologies. It is the use of technology that provides access to its users to various services that it provides. The emergence of this new technology allows users to access their files, software and computing power over the web. Many small scale businesses and organization can establish its infrastructure without the need for implementing actual hardware and software that are needed to build entire structure as it can entirely rely on the cloud services and use its resources on pay per use basis. But as coin has two sides so do the technology, with this advent of technology where data is easily stored and available on cloud; there are various threats challenging the data security and integrity.

The data stored on cloud is in shared form which invites the threats like loss or corruption of data due to software, hardware or human errors [3]. Moreover, the cloud service providers (CSP) may be reluctant to inform the data owner about the data theft or corruption due to fear of losing their reputation and business profit. So, to address this issue, Public Verifiers are used. A public verifier could be data user who would like to utilize the owner's data via cloud or third party auditor (TPA) who can provide expert integrity checking services.

There are many approaches [9][10] to check the correctness of the data stored on the cloud, like the traditional approach is to retrieve the entire data from the cloud to check its correctness. But, this approach wastes users' amount of computation and communication resources and of course the time and cost.

Thus the technique called Public Auditing [8] is being used to allow data owners and public verifiers to check the integrity of the data without the need to download the entire data from cloud. This mechanism divides data into many small blocks, where each block is independently signed by the owner; and a random combination of all the blocks instead of the whole data is retrieved during integrity checking. However this approach leads to an issue where the identity of the signer is revealed to public verifier leading to situation of leaked identity privacy. The public verifier will learn the identity of the signer on each block due to the unique binding between an identity and a public key via digital certificates under public key infrastructure (PKI).As a result, public auditing may put various confidential data at risk. In order to protect the confidential information, it is essential and critical to preserve identity privacy from public verifiers during public auditing.

The proposed paper will address above issue on shared data via novel mechanism that preserves privacy of data in public auditing. Ring signatures are utilized to construct homomorphic authenticators so that public verifier can check the integrity of shared data without disclosing the identity of the singer to public verifier. The batch auditing mechanism allows to perform multiple auditing tasks simultaneously.

A. System flow

As shown in figure 2.1, the system consists of three parties which are: cloud server, public verifier and group of users. The user can be the original user or group users. The original user is responsible for creating shared data in the cloud, and shares it with group users. Both the original user and group users are members of the group. Every member of the group is allowed to access and modify shared data. Both shared data and its verification metadata (i.e., signatures) are stored on the cloud server. A public verifier, such as a TPA who provides expert data auditing services or a data user outside the group intending to utilize shared data, is able to publicly verify the integrity of shared data stored in the cloud server. When a public verifier wishes to check the integrity of shared data, it first sends an auditing challenge to the cloud server. After receiving the auditing challenge, the cloud server responds to the public verifier with an auditing proof of the possession of shared data. Then, this public verifier checks the correctness of the entire data by verifying the correctness of the auditing proof.

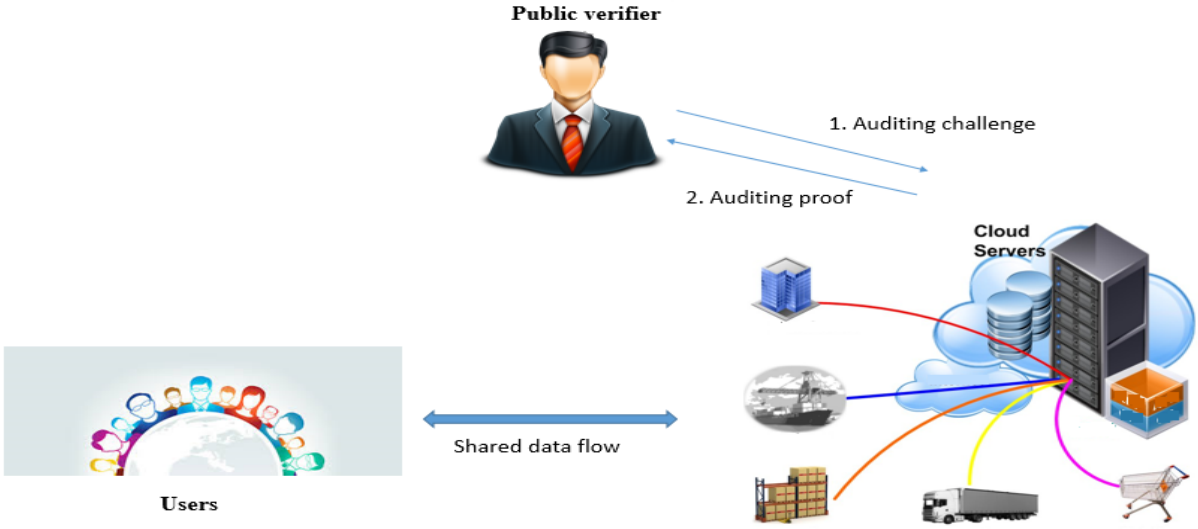

Fig 1: System model showing the cloud server, public verifier and group of users

B. Design goals

The main design objective is to design a system that will allow the public verifier to verify the integrity of shared data without retrieving the entire data from the cloud and without revealing the identity of the signer of each block. It must allow only a group users to generate valid metadata on shared data.

In order to preserve the identity of signer, we are creating the global private key which will be formed on behalf of all users in the group. This key can be used by all users of the group to sign the block. However, if any user leaves the group, it leads to regeneration of the global key which will be securely shared among the rest of the group. This however involves huge overhead of key management and key distribution.

C. Possible alternatives

Another possible approach to achieve identity privacy is to add a trusted proxy between a group of users and the cloud in the system model. More concretely, each member's data is collected, signed, and uploaded to the cloud by this trusted proxy, and then a public verifier can only verify and learn that it is the proxy signs the data, but cannot learn the identities of group members. Yet, the security of this method is threatened by the single point failure of the proxy. Besides, sometimes, not all the group members would like to trust the same proxy for generating signatures and uploading data on their behalf. Utilizing group signatures is also an alternative option to preserve identity privacy.

Trusted Computing offers another possible alternative approach to achieve the design objectives of our mechanism. Specifically, by utilizing direct anonymous attestation which is adopted by the Trusted Computing Group as the anonymous method for remote authentication in trusted platform module, users are able to preserve their identity privacy on shared data from a public verifier. The main problem with this approach is that it requires all the users to usedesigned hardware, and needs the cloud provider to move all the existing cloud services to the trusted computing environment, which would be costly and impractical.

II. PRELIMINARIES

A. Ring signatures

With the concept of ring signatures, the verifier understands that the signature is computed using one of the group members' private key but is not able to know which one. More concretely, given a ring signature and a group of users, say d, a verifier cannot distinguish the signer's identity with a probability more than 1/d. This property can be used to preserve the identity of the signer from a verifier.

B. Homomorphic Authenticators

Homomorphic authenticators (also called homomorphic verifiable tags) are basic tools to construct public auditing mechanisms. Besides unforgeability a homomorphic authenticable signature scheme, which denotes a homomorphic authenticator based on signatures, should also satisfy the following properties.

1. Block less verifiability

It allows a verifier to audit the correctness of data stored in the cloud server with a special block, which is a linear combination of all the blocks in data. If the integrity of the combined block is correct, then the verifier believes that the integrity of the entire data is correct. In this way, the verifier does not need to download all the blocks to check the integrity of data.

2. Non-malleability

It indicates that an adversary cannot generate valid signatures on arbitrary blocks by linearly combining existing signatures.

III. MODERN RING SIGNATURE SCHEME

The main motto of ring signatures [12] [13] is to hide the identity of the signer on each block in order to keep private and sensitive information un-disclosed to public verifier. However, the traditional ring signatures does not support block less verifiability and so the verifier needs to download the entire data from the cloud to check the correctness of the shared data which in turn consumes more bandwidth and more time. Therefore, it designs a new homomorphic authenticable ring signature (HARS) scheme, which is extended from classic ring signature scheme. HARS generated ring signatures are not only able to preserve identity privacy but are also able to support block less verifiability.

A. Construction of HARS

The HARS contains three algorithms: KeyGen, RingSign and RingVerify. In KeyGen algorithm each user in the group generates his/her public key and private key. In RingSign algorithm a user in the group is able to generate a signature on a block and its block identifier with his/her private key and all the group members' public keys. A block identifier is a string; it distinguishes the corresponding block from others. A verifier can check whether a given block is signed by a group member in RingVerify.

PUBLIC AUDITING MECHANISM

Using HARS and its properties, a privacy-preserving public auditing mechanism for shared data in cloud is constructed. In this scheme, the public verifier can verify the integrity of shared data without retrieving the entire data. The identity of the signer on each block in shared data is kept private from the public verifier during the auditing.

B. Reduce Signature Storage

Another important issue need to consider in the construction of this scheme is the size of storage used for ring signatures. By the taxonomy of the ring signatures in HARS, a block m is an element of Zp and its ring signature contains d elements of G1, where G1 is a cyclic group with order p. It means a |p|-bit block requires a d * |p| -bit ring signature, which forces users to spend a huge amount of space on storing ring

Volume 4, Issue 5, September 2015

signatures. It will be very frustrating for users, because cloud service providers, such as Amazon, will charge users based on the storage space they use.

To reduce the storage of ring signatures on shared data and still allow the public verifier to audit shared data efficiently, we exploit an aggregated approach to expand the size of each block in shared data into k *|p| bits. With the aggregation of a block, the length of a ring signature is only d/k of the length of a block. Generally, to obtain a smaller size of a ring signature than the size of a block, it choose k > d. As a trade-off, the communication cost of an auditing task will be increasing with an increase of k.

C. Support Dynamic Operations

To enable each user in the group to easily modify data in the cloud, there is a need to support dynamic operations on shared data. Dynamic operation such as insert, delete or update operation are performed on a single block. Since the computation of a ring signature includes an identifier of a block, traditional methods which only use the index of a block as its identifier are not suitable for supporting dynamic operations on shared data efficiently.

When a user modifies a single block in shared data by performing an insert or delete operation, the indices of blocks are changed after the block modification and the changes of these indices require users, who are sharing the data, to re-compute the signatures of these blocks, even though the content of these blocks are not modified. This mechanism can allow a user to efficiently perform a dynamic operation on a single block, and avoid the re-computation of indices on other blocks.

D. Batch Auditing

Sometimes, a public verifier may need to verify the correctness of multiple auditing tasks in a very short time. Directly verifying these multiple auditing tasks separately would be inefficient. By leveraging the properties of bilinear maps, the concept of batch auditing can be supported, which can verify the correctness of multiple auditing tasks simultaneously and improve the efficiency of public auditing.

IV. LITERATURE SURVEY

For some years, tools for defending against hackers have been in the form of software to be installed on each device being protected or appliances deployed on premise. However, to be effective, such protection needs to be constantly updated. Common methods for ensuring security of data in cloud consist of data encryption (cryptographic process) before storage, authentication process before storage or retrieval and constructing secure channels for data transmission. The protection methods find their routes in cryptographic algorithms and digital signature techniques.

The cryptographic algorithms are classified into two categories: symmetric and asymmetric algorithms. Symmetric algorithm uses a single key known as secret key both for encryption and decryption process whereas asymmetric algorithm uses two keys; one is the public key made available publically and the other one is the private key, which is kept secret used to decrypt the data. Breaking the private key is rarely possible even if the corresponding public key is known well in advance. Examples of symmetric algorithm comprise of Data encryption standard (DES), International data encryption algorithm (IDEA), advanced encryption standard (AES) on the other hand asymmetric key algorithm include RSA algorithm. Asymmetric algorithms are best suited for real world use and provides undeniable advantages in terms of functionality whereas symmetric algorithms is ideally suited for security applications like remote authentication for restricted websites which do not require full-fledged asymmetric set up. The use of passwords for authentication process is popular among the users but the transmission of messages containing password may be vulnerable to illegal recording by the hackers hence posing a security breach in the system. Some more advanced authentication techniques may employ the concept of single-usage-password where the system may generate challenge token expecting the user to respond with an encrypted message using his secret key which converts the password to some derived value enabling.

While using the cryptographic techniques for ensuring data security care should be taken for storing encryption and decryption keys. Rigorous methods should be adopted to prevent insiders and privileged user from gaining access to the encrypted data and decryption key simultaneously. Thus, the importance of SLAs is recognized in this context. The policies responsible for user data protection must be clearly mentioned in

Volume 4, Issue 5, September 2015

the provider's contract. After reviewing the data security requirements following recommendations have been included in multiparty SLA suggested at the end to ensure data security in cloud:

1. Encrypted data and decryption key must not be stored at the same place
2. Access control techniques should be applicable for malicious insiders and privileged users 3. Independent audits must be conducted to access the effectiveness of techniques employed for data storage.
4. Service providers must abide the ethics and legal laws and should be responsible for discrepancies if any
5. Backup and reset methods against system crash and failures.

In many applications, it is desirable to work with signatures that are both short and yet where many messages from different signers are verified very quickly. RSA signatures satisfy the latter condition, but are generally thousands of bits in length. Recent developments in pairing based cryptography produced a number of short signatures which provide equivalent security in a fraction of the space. Unfortunately, verifying these signatures is computationally intensive due to the expensive pairing operation. In an attempt to simultaneously achieve short and fast signatures, it was proved how to batch verify two pairing-based schemes so that the total number of pairings was independent of the number of signatures to verify. On the theoretical side, we introduce new batch verifiers for a wide variety of regular, identity based, group, ring and aggregate signature schemes. Our goal is to test whether batching is practical; that is, whether the benefits of removing pairings significantly outweigh the cost of the additional operations required for batching, such as group membership testing, randomness generation, and additional modular exponentiations and multiplications.

V. OBSERVATION

The observation of our proposed system led to the happening of the results mentioned below: 1. Encrypted data and key are stored separately on different storage media. 2. Before decrypting the data the user have to enter OTP which is sent on his mail and combination of OTP, key and encrypted data are used to generate original data. 3. For accessing the data the user is restricted in read only mode and for insert, modify and delete the notification is sent to admin. 4. After encryption or decryption the original data is deleted. 5. For securing the Account and Service Hijacking, we are eliminating the TPA. The work of TPA will be done by admin and our proposed system.

VI. CONCLUSION

This paper efficiently utilizes ring signatures for construction of homomorphic authenticators to hide the identity of the signer on each block. The proposed work allows the public verifier to audit the integrity of the shared data without retrieving the entire data hiding the identity of the signer. Thus, this paper effectively discusses the privacy preserving public auditing mechanism for shared data in the cloud.

ACKNOWLEDGMENT

I am thankful to Prof. Deepak Sharma for their logistical support and for providing necessary guidance concerning the implementation. Without whom this idea would have not come true. Without their superior knowledge and experience, the paper would like in quality of outcomes, and thus their support has been essential.
